

The Notion of Affinity in Semantic Structures

D. Gueorguiev 10/11/2021

Example:

Semantic structure S_1 :

"I live in and my name is."

$ssig(S_1) = [V_1 A_{1,2} V_2 A_{1,3} V_3 A_{1,4} V_4 A_{4,5} V_5 A_{5,6} V_6 A_{6,7} V_7]$

$text(V_1) = \text{"live"}$

$text(V_S) = \text{"a car"}$

$text(V_T) = \text{"Sofia"}$

$text(V_P) = \text{"Dimitar"}$

$text(V_Q) = \text{"Poison"}$

We have semantic particles which demonstrate affinity for specific properties. This means the particle attracts unconnected V -particles with specific combination of properties in their signature. It also demonstrates anti-affinity i.e. repels unconnected V -particles which have different combination of properties in their signature.

Affinity field of the semantic structure S – a discrete field which defines affinity / anti-affinity force $F(V_i)$ between the particle V_i of the semantic structure S and a test particle $V_{test}(P)$

$F(V_i, V_{test}) = F_i(P), i \in \mathbb{V}(S)$

$\mathbb{V}(S)$ denotes the set of indices of the V -particles in the semantic structure S

P is the properties tree $ptree(V_{test})$ of the test particle V_{test} . We will assume general form of P .

The affinity force $F_i(P)$ is a function that maps the property tree P to a signed real number. The function $F_i(P)$ identifies specific features of the property tree such as the presence of specific subtree $\mathfrak{T} \subset P$ or a specific set of properties $\mathcal{S} \subset P$ toward which V_i has strong affinity (attraction). Note that F_i has implicit dependence on S as well i.e. in a context different than S F_i could have different values for the same P .
